

Positronium decay (Ps)

The **positronium** is a bound state of the electron and positron similar to a Hydrogen atom. The positronium can be produced from positrons emitted from β^+ decays.

The energy levels of the positronium are similar to the one of the Hydrogen atom.

The energy spacing is smaller by a factor of 2 because the reduced mass of the positronium is lower by a factor 2.

Positronium

$$m_{ee} = \frac{m^2}{2m} = \frac{m}{2}$$

Hydrogen

$$m_{ep} = \frac{M \cdot m}{M + m} \approx m$$

Levels of the Positronium (Ps)

$$E_n = -\frac{\mu \cdot e^4}{8 \cdot h^2 \varepsilon_0^2} \frac{1}{n^2} = -\frac{6.8}{n^2} \text{ eV}$$

μ = reduced mass

n = principal quantum number

$$r_{1s} = 2 \times 0.53 \cdot 10^{-8} \text{ cm}$$

The lowest lying level splits in two states:

- **parapositronium** (lifetime **125 ps**), the electron and the positron have **antiparallel spin**, coupled to $S=0$. This state annihilates mainly in **two photons** with opposite directions, each one having energy 511 keV.

- **orthopositronium** (lifetime **142 ns**), the electron and the positron have **parallel spin**, coupled to $S=1$. This state annihilates in **three photons** with energies and directions satisfying conservation of energy and momentum.

In vacuum, **one forth** of the bound states of **Ps** are formed in a state with **S=0**, while **three forth** are formed in a triplet state with **S=1**

In order to preserve angular momentum and respect CP (Charge and Parity) invariance, a positronium in a state of spin S and orbital momentum L annihilates according to the following **selection rule**:

$$(-1)^{n_\gamma} = (-1)^{L+S}$$

Parapositronium $n_\gamma = 2, 4, \dots$

Orthopositronium $n_\gamma = 3, 5, \dots$

The ratio between the decay channel in **three photons** and that one in **two photons** is 1/373. It is a consequence of the ratio between the lifetimes of the two states and of their phase space

125 ps for the **Parapositronium**

142 ns for the **Orthopositronium**

The Three-Photon Annihilation of Positrons and Electrons*

S. DEBENEDETTI AND R. T. SIEGEL†

Carnegie Institute of Technology, Pittsburgh, Pennsylvania

(Received January 22, 1954)

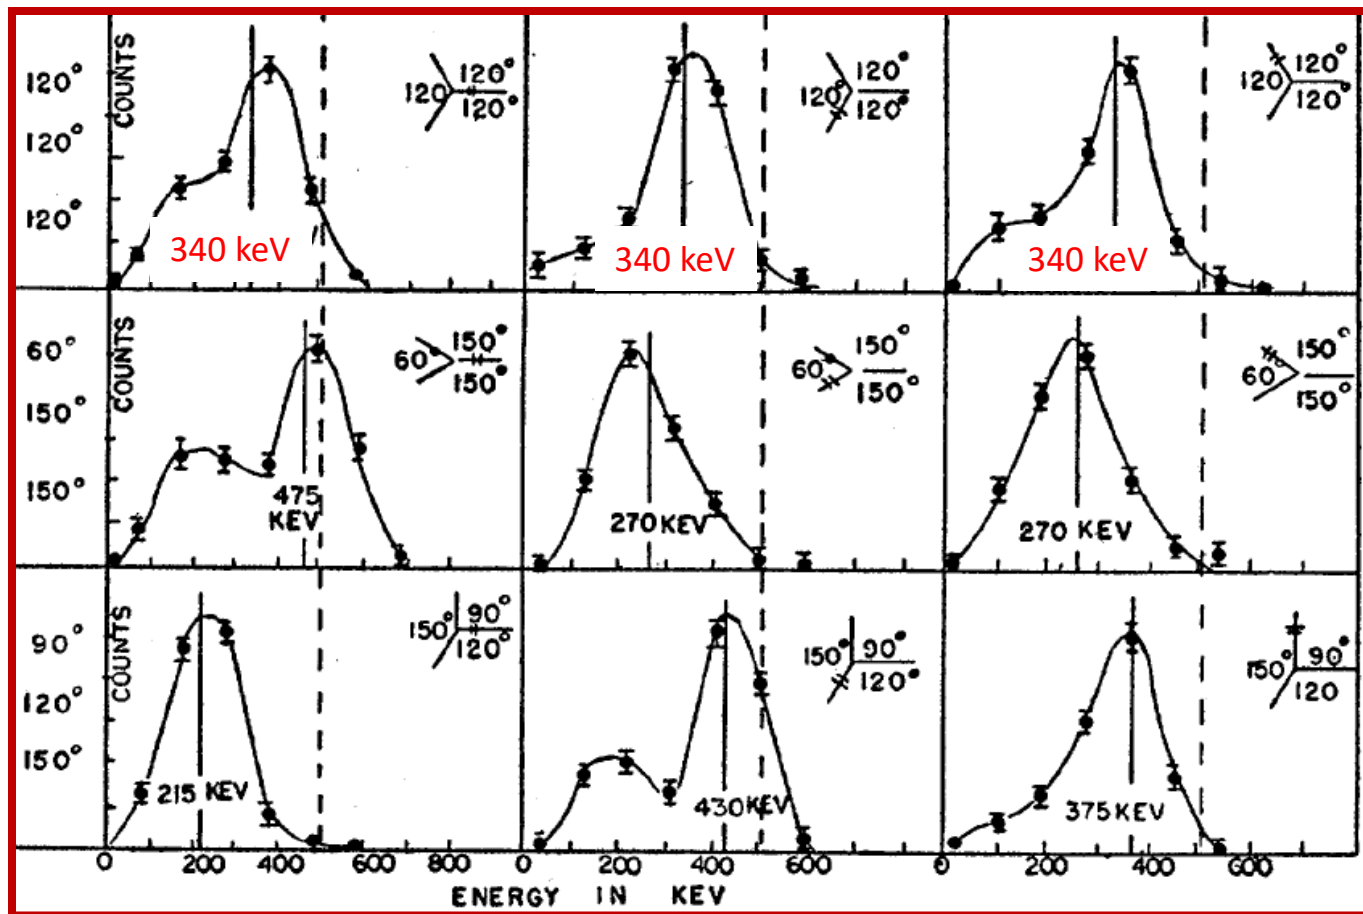

Angles between counters			Energy in each counter (kev)		
2-3	3-1	1-2	E_1	E_2	E_3
*120°	120°	120°	341	341	341
*90°	120°	150°	430	215	375
*60°	150°	150°	475	272	272

The three NaI(Tl) detectors lay on the same plane. The **annihilation takes place at rest** and as a consequence the total momentum is negligible. The sum of the momenta of the two (or three) photons must be negligible.

2 γ decay in line

3 γ decay in the same plane

The expected energies for each of the detectors are reported. Their sum must be **1022 keV**

As a consequence of the conservation of linear momentum and energy, the energies of the three photons depend on the emission angles. If the three detectors have a symmetrical configuration with 120 deg in between them, the three photons must have the same energy, i.e. 340 keV.

The ratio ($\sim 1/370$) between the annihilation events in 3γ and that one in 2γ has been verified to have a slight dependence on the material where the positronium annihilates

Lifetime of the positron decay in matter

In vacuum the orthopositronium decays with $\tau = 142$ ns. In matter the lifetime depends on the type of material.

In this experiment with mesoporous silicon two components were measured, one with

$$\tau_1 = 25.03 \pm 0.3 \text{ ns}$$

The other with

$$\tau_2 = 140 \pm 7 \text{ ns}$$

Positrons have a wide use in nuclear medicine, for example in

Positron Emission Tomography (PET)

Compounds with a small contents of radioisotopes with short lifetime such as the nuclei ^{11}C or ^{18}F (β^+ emitters) can be injected and can be traced till they concentrate in specific tissues or organs. It is possible to trace them because they decay by **positron emission** that annihilates with the electrons and yield **two gammas of 511 keV** in opposite direction.

The organ has to be surrounded by detectors that can detect the gamma radiation emitted

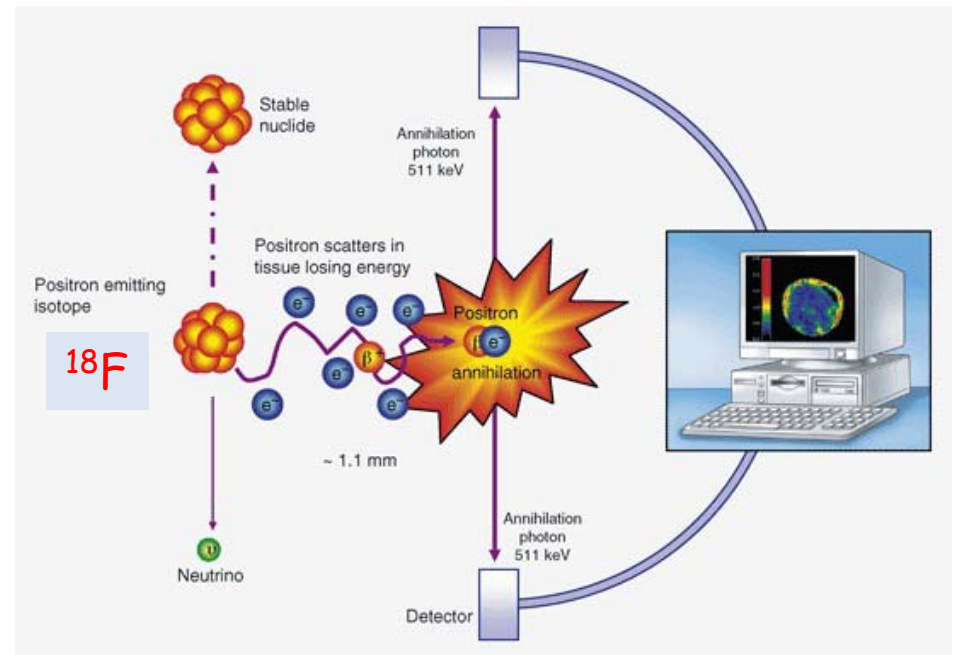

When two detectors detect the arrival of **two photons in time coincidence** it is reasonable that the two photons were emitted by the **same annihilation decay**. The position where there was the decay of the ^{11}C , ^{13}N or ^{18}F must be along the line connecting the detectors that fired.

Identifying many couples of photons, exploiting many crossings, it is possible to guess the position or **distribution of the radioactive elements**.

Following the processes for a proper amount of time it is possible to obtain a map of the changes in concentration of the elements.

This paves the way to a functional study of the heart, the brain or other organs, with the possibility of diagnosing their functional problems.

PET images show a lowering of the consumption of glycogen associated to a weakened cognitive capacity as a consequence of the Alzheimer disease. The fluorodeoxyglucose [^{18}F]FDG is commonly used.

Goals of the experience are a) measurement of the **ratio** between positron decay in two photons and decay in three photons

^{22}Na source

b) measurement of the **time distribution** of the events

The **two or three gammas** emitted in coincidence will be measured by **three scintillator detectors NaI(Tl) 4" x 4"**

laying in the same plane. A forth **NaI(Tl)** is positioned on top, in an orthogonal direction to that plane.

The three detectors are mounted on a rotating arm that allows the variation of the **angle in between them**.

Two configurations will be used:

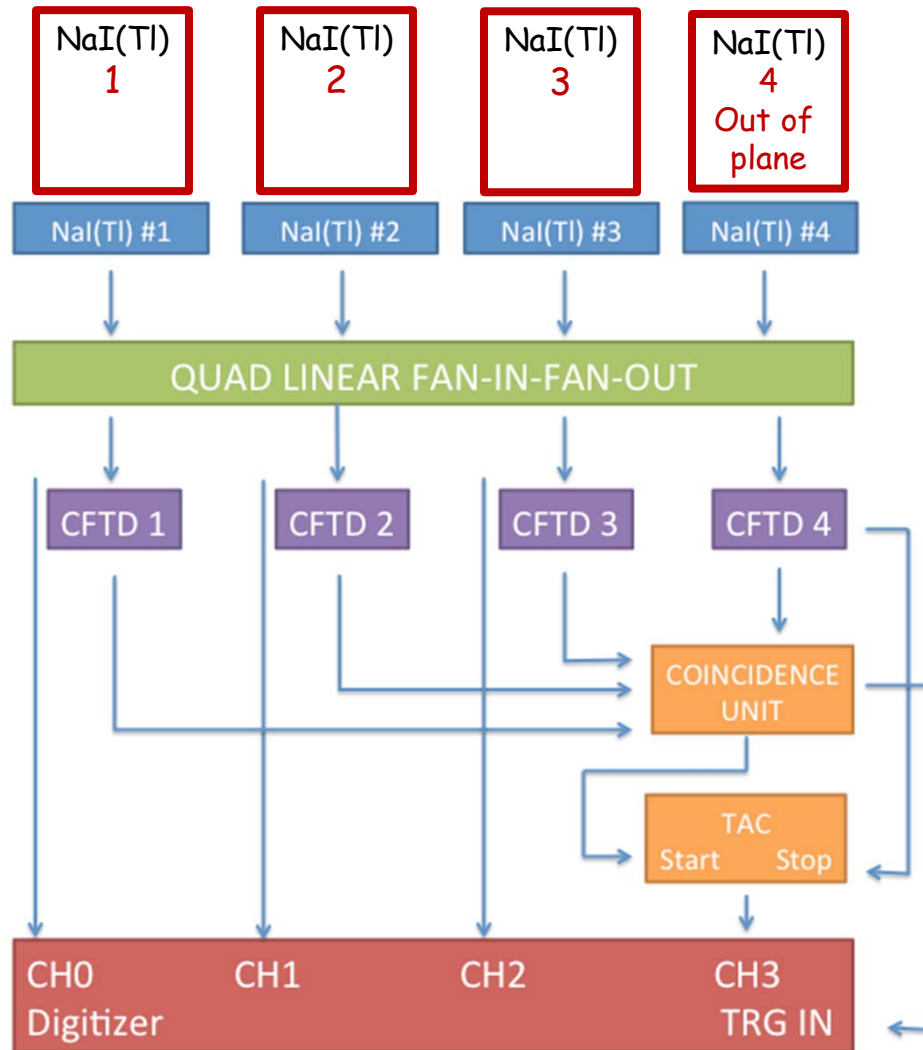

Three-gammas decay

Two-gammas decay

Electronics layout

The three detectors 1, 2 and 3 are taken in coincidence in between them and also in coincidence with the 1274 keV gamma in detector 4 out of plane.

Energy calibration of the 4 NaI(Tl) detectors

Detector 1

Detector 2

Detector 3

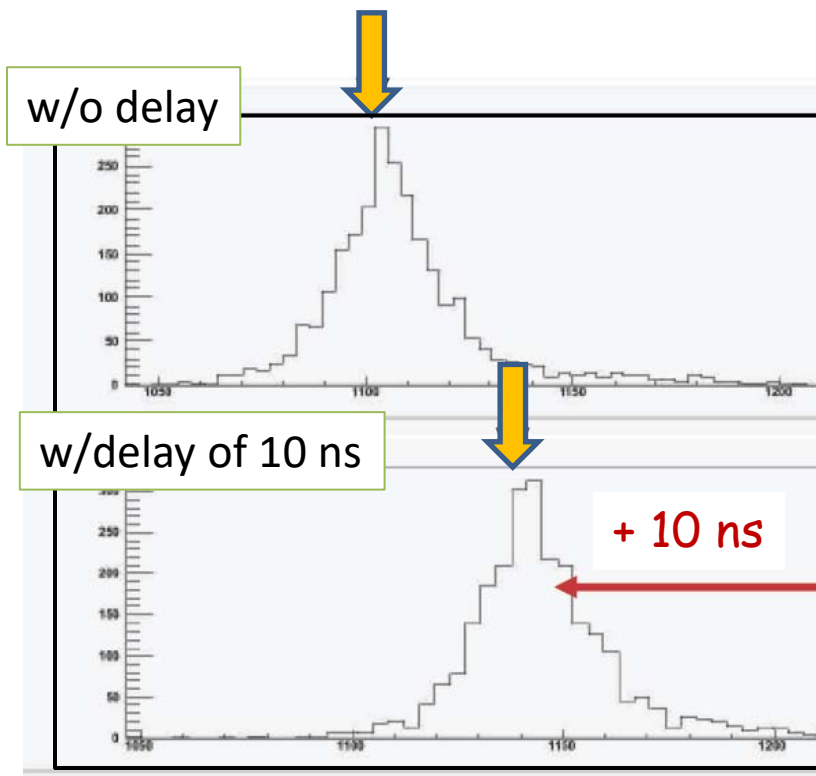

Detector 4

TAC calibrations (Time to Amplitude Converter)

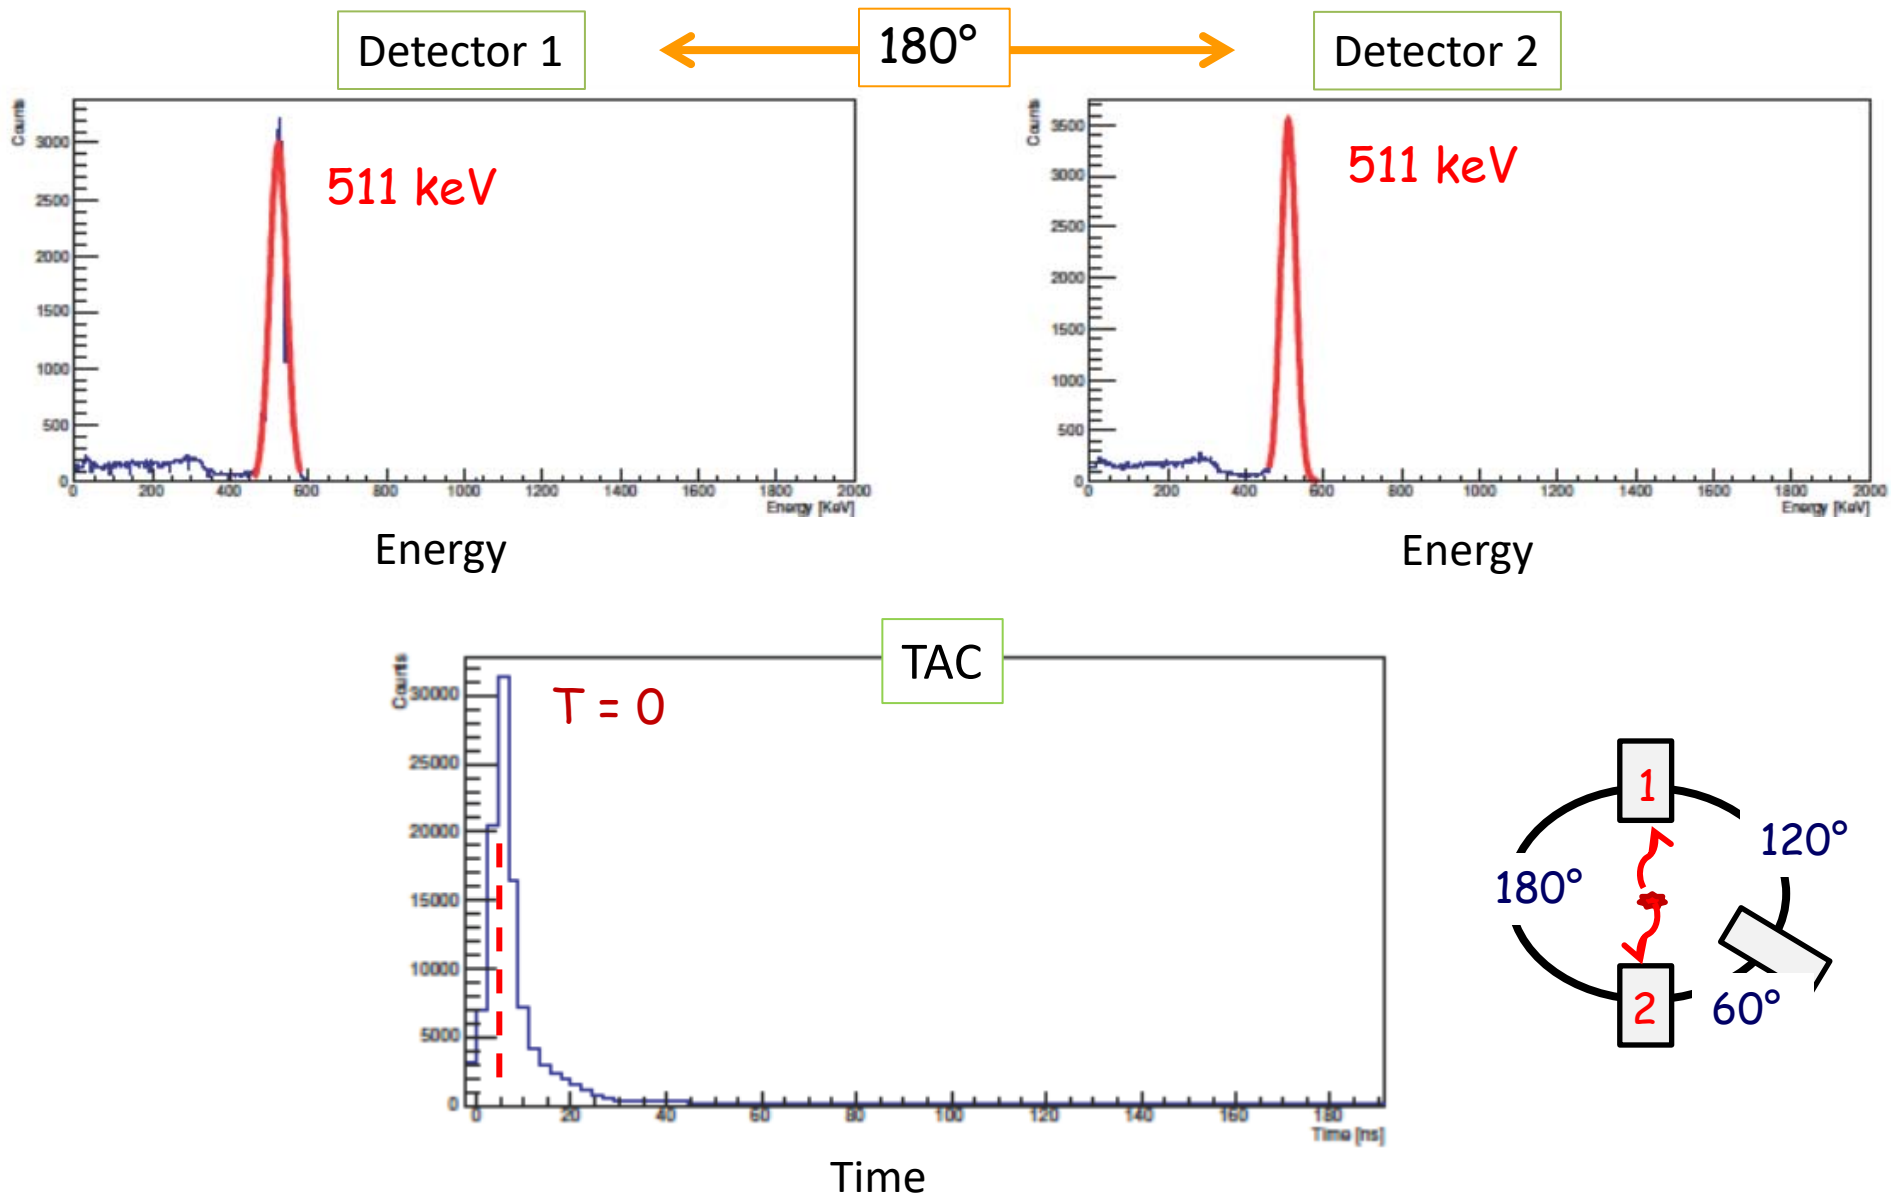

In order to measure the coincidence between the positronium decay in two or three photons and the γ decay of ^{22}Ne populated by β -decay.

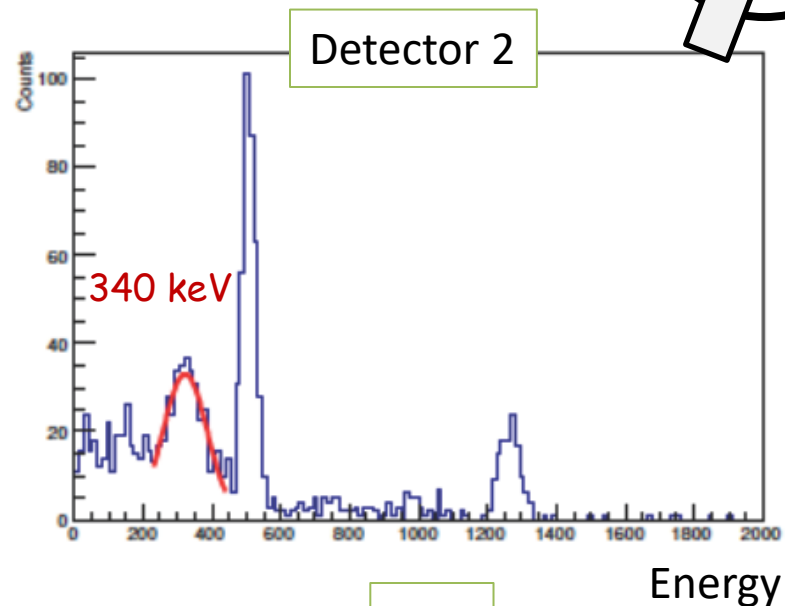

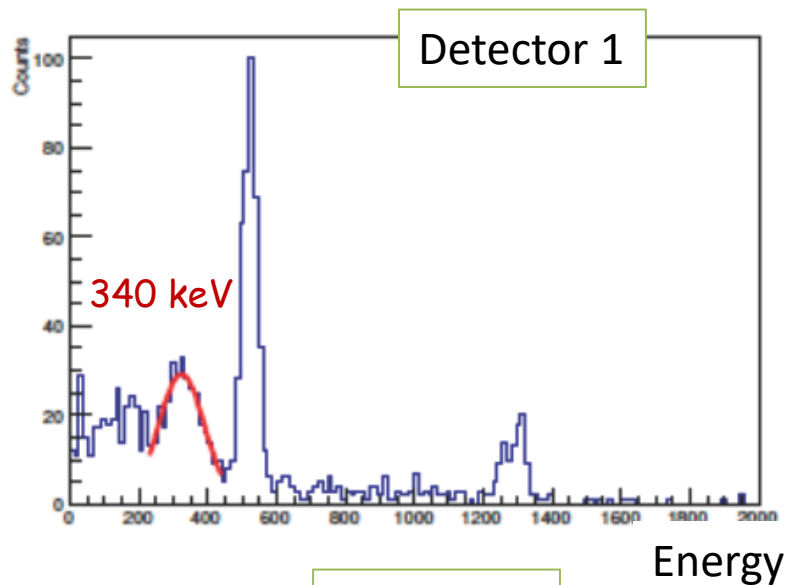

TAC calibration

Results: two photons decay

Results: three photons decay

Sum gamma spectra: the energies measured by each detector are summed and incremented in a spectrum $\rightarrow \Sigma = 1022 \text{ keV}$

Sum spectrum: **three** photons decay

In order to measure the three gamma decay we have to wait for a long time!!

Sum spectrum: **two** photons decay

Summarizing, the goals of the Positronium experiment are'

- a) to verify the ratio in between the **two photons decay** and the **three photons** decay of the positronium
 - b) to measure the **timing distribution** of the events for the two tyoes of decay
-
- First session: preparation and calibration of the scintillators
 - Second session: setup of the coincidences and measurement of the decay in two gammas (short) and three gammas (full night)
 - Third session: measurement of the time distribution of the events
